

Determining the Solar Index  
for Madison, Wisconsin

THE SCHWERDTFEGER LIBRARY  
1225 W. Dayton Street  
Madison, WI 53706

by

Charles R. Stearns

### I. Introduction

The solar index is the fraction of daily hot water that can be delivered by a hypothetical solar hot water system. The daily usage by a family of four is assumed to be 80 gal of water at 50°C. This corresponds to a solar index of 1. The initial water temperature is 10°C, so that a solar index of 0.5 would correspond to 80 gal of water heated from 10°C to 30°C during the day. The hypothetical collector area is 60 sq ft, and the collector is tilted up at 45° to the horizon with the fall line pointing due south.

### II. Method

A solar collector was constructed with a black copper receiving surface 30 cm X 60 cm insulated on the back with 10 cm of fiberglass insulation and covered with one pane of single strength window glass. The sides are 2" x 4" and the back is covered with 1/4" plywood. A single junction thermocouple measures the temperature of the copper plate at a point 45 cm up from the bottom and another thermocouple measures the temperature difference from 15 cm to 45 cm. The solar collector is mounted at 45 deg from the horizon and the fall line is approximately south.

The heat budget of the collector can be written as

$$[BI \cdot \cos(SCA) + DI \cdot SA + (BI \cdot \cos \zeta + DI)(1-SA)a] \cdot a_g^c + [LW^+ \cdot SA + LW^+ \cdot (1-SA)] \cdot a_L^c = S + Q + a_L^c \sigma T_c^4$$

where

BI = beam solar radiation from the sun

SCA = sun-collector angle

DI = Diffuse solar radiation from sky

SA = fraction of sky seen by collector

$\alpha_s^c$  = absorbtivity of collector for solar radiation

$\zeta$  = sun's zenith angle

a = surface albedo of area in front of the collector

LW $\downarrow$  = long wave radiation from sky

LW $\uparrow$  = long wave radiation from the ground

$\alpha_L^c$  = absorbtivity of collector for long wave radistion

S = heat removed from collector

Q = collector heat loss to air

$\sigma$  = Stefan Boltzmann constant

$T_c$  = collector Kelvin temperature

The solar collector does not have heat removed so that the temperature which is measured is the temperature for S = 0.

The assumption is made that the energy for removal from the collector to heat the water will lower the collector temperature to the water temperature.

Then

$$S = \alpha_L^c \sigma (T_c^4 - T_w^4)$$

where

$T_w$  = water temperature

S = energy/area/time

and must be positive. By this method if the water temperature is above the collector temperature or the collector temperature is below 21°C, no energy is delivered to the water.

The hypothetical solar hot water heater is of 60 sq. ft. area and has a capacity of 80 gal. of water or 10.67 lbs. of water per sq. ft. of collector. The initial water temperature is 10°C and for a solar index of 1 or 100% the final water temperature is 50°C. The solar index is calculated as the fraction of the water temperature rise from 10°C.

The solar collector temperature is the linear average of the top and bottom temperature. Measurements are made every 30 minutes and the amount of energy available per sq. ft. for 30 minutes is used to raise the temperature of the storage water. The water temperature can change as much as 5°C in 30 minutes but the change in  $T_w^4$  during this time is neglected. An efficiency factor of .81 is used as the heat transfer is not perfect in practice. The decrease in Q due to the lower collector to air temperature difference is also neglected.

The above method does not follow the conventional engineering approach.

### III. Experimental Set-up

The sensor location is the south side of the roof of the Meteorology and Space Science Building located at 1225 W. Dayton Street, Madison, Wisconsin. The roof top is surrounded by a parapet five or more feet high. The penthouse to the north has two satellite antennas mounted on the south side and painted white which can reflect sunlight onto the sensors. The penthouse obscures most of the northern sky.

The solar collector is mounted on a frame about 2.5 ft. off the deck and thus slightly below the parapet. The pyrheliometer with equitorial

drive is mounted on the same frame. In back and about 4 ft. higher is a board on which are mounted two Eppley pyranometers.

The thermocouples measuring air temperature and collector temperature are referenced to an oil filled thermos bottle in room 1547 and the reference temperature is assumed to be 20°C.

The actual measurements made and the sensors are:

1. collector temperature near top-thermocouple
2. collector temperature difference-thermocouple
3. air temperature-thermocouple
4. beam solar radiation-solar cell pyrheliometer
5. global solar radiation - two Eppley pyranometers
6. solar radiation on collector - solar cell.

The recording system is a 0 - 2.5 mv Brown recorder located in room 1325. The recorder cycles through the data every five minutes between 8:00 a.m. and 5:00 p.m.

#### IV. Data Processing

Once each week the data is digitized to punch cards using a digitizing table. The year, Julian date and time are initially punched on the card. Then channels 1 through 9 are entered in order corresponding to the same channel number printed by the recorder. Full scale on the chart is 550 units and the resolution is  $\pm 1$  unit.

The instruments are occasionally intercalibrated by shading the two pyranometers and the solar cell from the sun's beam radiation. The intercalibrations are included in the data set as is the program for processing the data.

## V. Presentation of Results

The printed output from the original data consists of year, Julian day and time followed by the data and computations in units of Watts $\cdot m^{-2}$  for

PHR - pyrheliometer measuring beam solar radiation

GLOB1 - pyranometer measuring global solar radiation

GLOB2 - pyranometer measuring global solar radiation

SOLCL - solar cell measuring solar radiation falling on the collector

EM -  $\sigma T_c^4$  of the collector

EM1 - solar radiation falling on collector calculated from PHR and GLOB1

EM2 - solar radiation falling on collector calculated from PHR and GLOB2  
then in °C.

TA - air temperature behind collector

TCOL - average collector temperature

TW - hypothetical water temperature

The printout at the end of each day is year, day, number of cards in day, solar index, equivalent BTU's  $ft^{-2}$ , Watt hrs  $m^{-2}$  and the cumulative watt hrs  $m^{-2}$  from the solar cell.

Data collection started 17 September 1978. The pyranometers used at that time were not satisfactory so the only data presented are the temperatures. On October 13, 1978 two good Eppley pyranometers were installed along with the solar cell at the tilt of the collector. By this time the pyrheliometer was no longer operational. On November 2, 1978 the pyrheliometer sensor was replaced by a solar cell and calibrated against the two Eppley pyranometers on 2 Nov. 1978. On 28 Oct. 1978 the chart ran out over the weekend and recording did not commence until 1000 30 October 1978.

The present calibration is based on the manufacturer's calibration of the Eppley pyranometers. A new Eppley pyrheliometer has been ordered at a cost of \$890 and will be used as the standard in the future.

Fig. 1 gives the weekly average solar index for Madison, Wisconsin for the measurement period in 1978. Fig. 2 shows the relationship between the daily solar index and the watt hours per day falling on the solar cell at the collector orientation. Approximately 1000 watt hours per day are required before the collector delivers useable energy above 21°C.

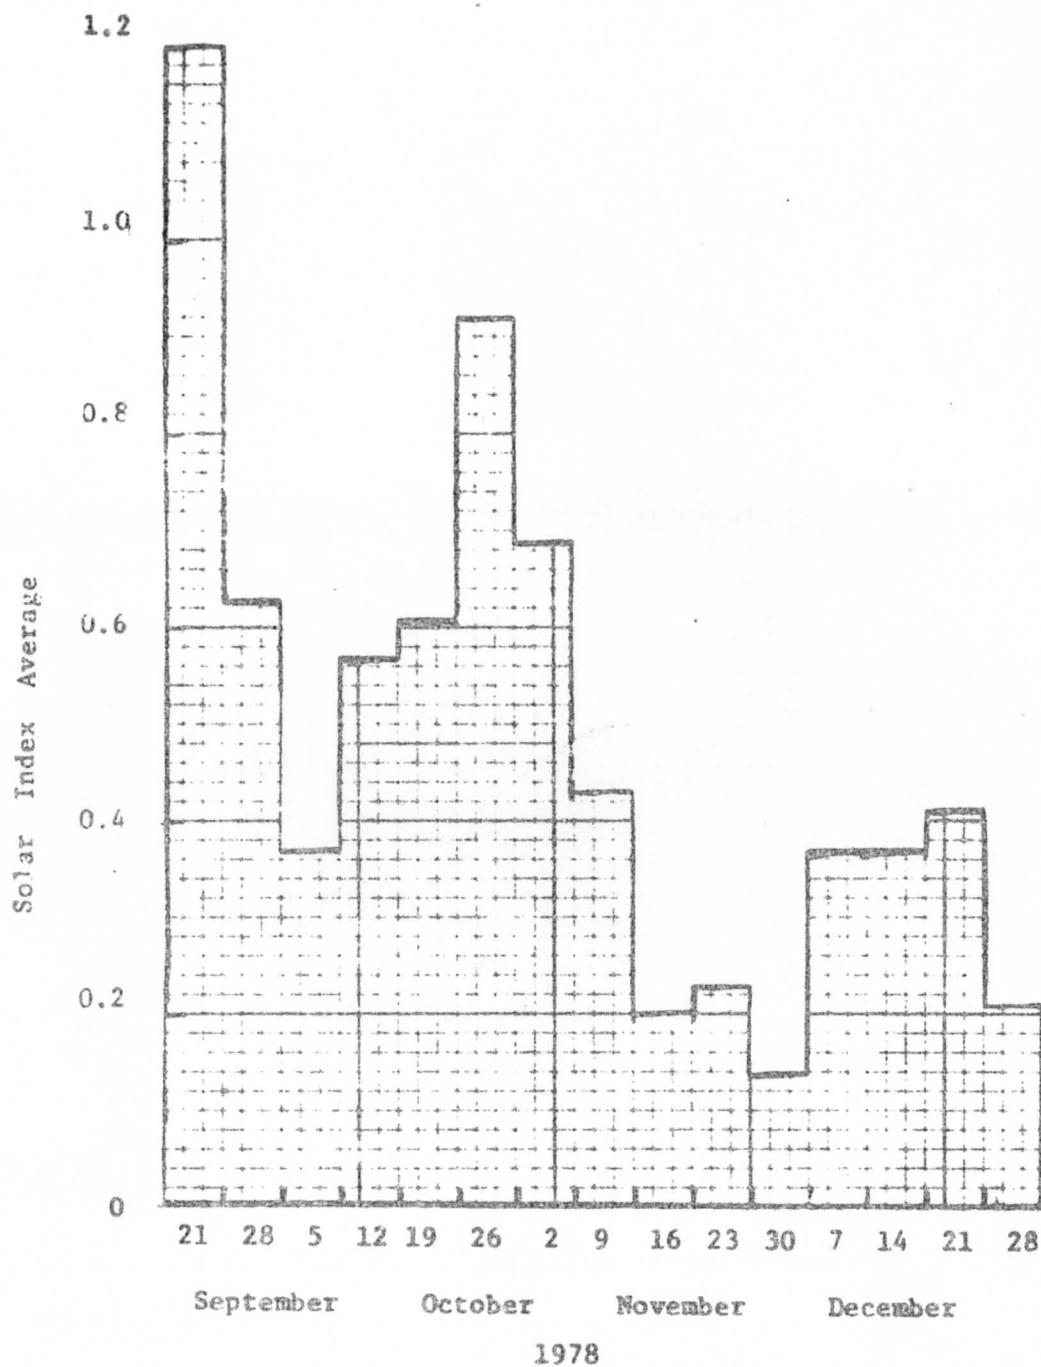

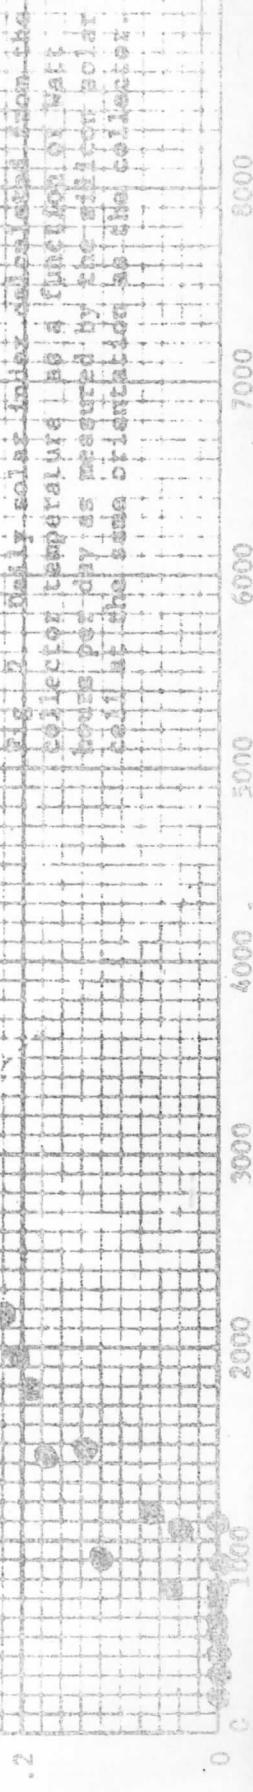

Fig. 1. Weekly average of the solar index for Madison, Wisconsin as a function of the date of the first day of the week which is a Thursday. The period is 21 September 1978 to 3 January 1979.
